ABSTRACT

The pronounced and persistent impact of the global financial crisis of 2008 motivates our empirical analysis of the role of institutions and macroeconomic fundamentals on countries' adjustment to shocks. Our empirical analysis shows that the associations of growth level, growth volatility, shocks, institutions, and macroeconomic fundamentals have changed in important ways after the crisis. Gross domestic product growth across countries has become more dependent on external factors, including global growth, global oil prices, and global financial volatility. After accounting for the effects global shocks, we find that several factors facilitate adjustment to shocks in middle-income countries. Educational attainment, share of manufacturing output in gross domestic product, and exchange rate stability increase the level of economic growth, while exchange rate flexibility, education attainment, and lack of political polarization reduce the volatility of economic growth. Countries cope with shocks better in the short to medium term by using appropriate policy tools and having good long-term fundamentals.

I. INTRODUCTION

The global financial crisis of 2007–2009 marked a watershed moment in postwar economic history of the world. Prior to the global crisis, most financial and economic crises occurred in emerging markets in Asia and Latin America. While those crises inflicted a great deal of economic and social hardships on the affected economies, the spillover effects of those crises on other economies were, by and large, limited. For example, the Asian financial crisis of 1997–1998 sharply curtailed growth and caused high unemployment and other humanitarian suffering in four high-flying East and Southeast Asian economies namely, Indonesia, the Republic of Korea, Malaysia, and Thailand, but those effects did not spill over to the rest of the world. Similarly, the adverse effects of the crises that Argentina, Mexico, and other Latin American countries suffered prior to the global crisis were mostly confined to the crisis-hit economies themselves.

What is qualitatively different about the global financial crisis was that it broke out in the United States (US), the world's largest economy and home to the world's biggest, deepest, and most liquid and sophisticated financial markets. As such, it was bound to have incomparably larger effects on the rest of the world and so it proved. The crisis was rooted in the US subprime mortgage crisis which, in turn, was rooted in colossal market failures in the US housing and financial markets. Simply put, in their quest for yield, US banks lent far too much mortgage to borrowers with poor credit ratings, fueling a housing bubble that burst when Lehman Brothers went under. The crisis paralyzed credit flows in the US and spread like wildfire across the Atlantic to Europe, due to the heavy exposure of many European banks to US subprime mortgage assets. The primary channel of crisis transmission to emerging markets was via reduction of trade and disruption of capital flows.

As credit flows seized up, business and consumer confidence took a major hit, and investment and consumption plummeted, crimping growth. Thus, the global crisis spread quickly from the financial markets to the real economy. The US and other advanced economies went into recession and, in 2009, suffered a contraction of output. Although emerging markets as a whole grew in 2009, emerging market growth was not enough to offset advanced economy contraction, and global gross domestic product (GDP) fell marginally for the first and only time in the postwar period (Figure 1). While the decline in global GDP was marginal, the decline in global trade was more substantial (Figure 2). When the global crisis broke out, there were genuine, widespread fears of another Great Depression, the interwar catastrophe that devastated the world economy. In fact, only concerted, forceful fiscal and monetary policy interventions by governments and central banks around the world averted another Great Depression.

There is a visible slowdown of global growth momentum since the global financial crisis. In other words, the effects of the crisis continue to reverberate. Initially, the slowdown was more evident in the advanced economies, giving rise to the notion of a two-speed economy of fast-growing emerging markets and slow-growing advanced economies. However, in more recent years, the growth deceleration has spread to emerging markets, causing the world economy as a whole to slow down. Thus, the effect of the global financial crisis on global growth is significant and persistent. In addition, a number of structural factors also contributed to the weakening of the world economy since 2008. For example, the People’s Republic of China’s growth has moderated in recent years, largely due to structural factors such as population aging, convergence toward high income, and rebalancing toward domestic demand.

Above all, population aging is not confined to the People’s Republic of China, but poses an increasingly global headwind against growth. Whereas the demographic transition toward older population structures was almost exclusively a rich-country trend, in recent decades it has spread to developing countries, including much of Asia (Figure 3).

While structural factors such as population aging are also at play, the size and persistence of the slowdown of global growth momentum since the global financial crisis suggests that it is worthwhile to examine and compare vulnerability with economic shocks before and after that crisis. While it is admittedly too early to tell whether the global crisis will permanently lower the global growth trajectory, nevertheless it has so far been a game changer that has had profound effect on the global economic and financial landscape. One natural question that arises is whether vulnerability and adjustment to shocks have changed in fundamental ways since the crisis. While this question is relevant for all countries, it is perhaps especially relevant for middle-income countries in light of their growing integration into the world economy. For example, whereas much of foreign capital, which flows into low-income countries, are foreign aid and foreign direct investment in natural resource industries, middle-income countries receive greater amounts of potentially volatile short-term capital inflows, rendering them more vulnerable to shocks. Further, the policy tools and institutions for coping with shocks tend to be less developed in middle-income countries than in high-income countries. Of particular interest is the volatility and level of growth.

The rest of this paper is organized as follows. Section II briefly reviews the literature of studies that examine the factors which hinder or facilitate smooth growth adjustment to macroeconomic shocks. Section III describes the data and empirical framework. Section IV reports and discusses the main empirical findings. Section V concludes the study.

II. SELECTIVE LITERATURE REVIEW

A key feature of developing countries is their greater exposure to domestic and external macroeconomic shocks than the industrial countries (Hausmann and Gavin 1996). Understanding the root causes of this exposure and the ways to mitigate it remains a vibrant research agenda. This section provides a selective review of the recent literature on this important issue. The higher volatility of developing countries reflects the larger size and greater volatility of exogenous external shocks, such as terms of trade volatility, greater vulnerability of developing countries to such shocks, which is sometimes exacerbated by volatile domestic policy, along with limited absorption and adjustment capacities.

While the association between shocks, investment, and economic growth is generally ambiguous (Caballero 1991 and the references therein), the empirical research during around the mid-1990s convincingly showed a negative association between macroeconomic volatility and growth. Pindyck and Solimano (1993) showed that decade-to-decade changes in volatility have a moderate effect on investment, and the effect is greater for developing countries than for industrialized countries. Aizenman and Marion (1993) showed that policy uncertainty is negatively associated with private investment and growth in developing countries. Ramey and Ramey (1995) found a negative association between growth and volatility in a comprehensive study that included the Organisation for Economic Co-operation and Development and the developing countries.¹ The study linked volatility to the debate about the cost of the business cycle.²

A seminal paper by Rodrik (1999) identified weak institutions and latent social conflict as the main reasons for the negative impact of volatility on growth. Rodrik (1999) emphasized the manner in which social conflicts interact with external shocks on the one hand, and the domestic institutions of conflict management on the other. Countries that experienced the sharpest drops in growth after 1975 were those with divided societies, as measured by indicators of inequality, ethnic fragmentation, and the like, and with weak institutions of conflict management, proxied by indicators of the quality of governmental institutions, rule of law, democratic rights, and social safety nets. The implication is that strong institutions dampen volatility, while weak institutions magnify the negative consequences of volatility.

Easterly, Islam, and Stiglitz (2000) honed in on the financial system as the primary factor in growth volatility. They found that, up to a point, greater financial depth is associated with lower growth volatility; but as financial depth and leverage grow, the financial sector could become a source of macroeconomic vulnerability. Aghion et al. (2009) offered empirical evidence that real exchange rate volatility can have a significant impact on long-term rate of productivity growth, but the effect depends critically on a country's level of financial development.

Acemoglu et al. (2003) took the primacy of institutions a step further, arguing that crises are caused by bad macroeconomic policies, which increase volatility and lower growth. But more fundamentally, bad macro policies are the product of weak institutions. To avoid problems with endogeneity and omitted variables, they developed a technique to isolate the historically determined

¹ Ramey and Ramey (1995) failed to detect a negative association of macro volatility to investment. Aizenman and Marion (1999) noted that Ramey and Ramey (1995) reflect their focus on aggregate investment, but there is a robust negative association of macro volatility and private investment.

² These results are in sharp contrast to Lucas (1987), who showed, in a calibrated model, that the cost of business cycle volatility is of second order magnitude. Lucas' results reflected his presumption that the economic growth is independent from business cycle volatility, a presumption that is not supported by the data.

component of institutions, based on the colonization strategy pursued by European settlers, and show that this is the critical factor in explaining volatility, crises, and growth.

Macroeconomic volatility depends on economic structure, e.g., sectoral composition of output, trade openness, financial openness, as well as on the economy's institutional structure and economic policy regimes. While the openness of the economy may be given in the short run, in the long run it is the endogenous outcome of geography, history, demographics, policies, institutions, and other factors. We review below several of these channels.

Inter-American Development Bank (IDB) (1995) and Hausmann and Gavin (1996) found that higher volatility was associated with both lower growth and higher inequality, with the latter tending to be highly persistent. The impact of volatility on inequality was transmitted mainly through educational attainment. Further, institutional shock absorbers are important determinants of macroeconomic volatility. Specifically, deep financial markets act as a shock absorber. Further, the exchange rate regime has a significant impact on volatility. In particular, pegged exchange rate regimes appear to stabilize the real exchange rate, at the cost of destabilizing real output. Switches between exchange rate regimes are highly destabilizing, suggesting that unsustainable regimes are destabilizing.

The follow-up literature provided ample evidence that, for developing and emerging market countries, less flexible exchange rate regimes are associated with slower growth, as well as with greater output volatility (Broda 2004, Edwards and Levy-Yeyati 2005, and Céspedes and Velasco 2012). In a related research by the IDB, Gavin et al. (1996) identified the procyclicality of fiscal policy as a major amplifier of developing countries' vulnerability to shocks. Remarkably, over the last 2 decades, the fiscal policies of about a third of developing countries have become countercyclical. Chile is a case in point, with institutional design facilitating smoother countercyclical adjustment of fiscal and other macroeconomic policies (Frankel 2011; and Frankel, Vegh, and Vuletin 2013).

This discussion can be framed in the broader context of influential changes in the configuration of Mundell's Trilemma following the collapse of the Bretton Woods system. Remarkably, emerging markets increased their financial integration in the 1990s, a process that heightened their vulnerability to shocks. In some vulnerable countries, capital flight induced banking and balance-of-payment crises, crises that were dubbed as "sudden stop crises" by Calvo (1998) and Calvo and Reinhart (2000), and studied by Eichengreen, Gupta, and Mody (2008). The position of developing countries was further compromised by their inability to borrow in their own currency—the original sin articulated by Eichengreen, Hausmann and Panizza (2002)—and by their limited and uncertain access to capital markets due to high sovereign risk.

In line with the trilemma (i.e., impossible trinity) prediction, over time the growing financial integration of emerging markets came at a cost of lower exchange rate stability, i.e., greater managed flexibility of the exchange rate. Through a trial-and-error learning process, emerging markets gradually found the trilemma middle ground—greater exchange rate flexibility, limited financial integration, and controlled monetary independence, buffered by macroeconomic prudence. This approach is evident in the precautionary hoarding of international reserves, aimed at reducing the frequency and the costs of capital flight crises.

Relevant studies include Aizenman and Lee (2007); Aizenman, Chinn, and Ito (2011, 2013); and other papers listed in Aizenman, Chinn, and Ito's trilemma indexes webpage (http://web.pdx.edu/~ito/trilemma_indexes.htm). They found that greater monetary independence is associated with lower output volatility, while greater exchange rate stability is associated with greater

output volatility, which can be mitigated if a country has sizable international reserves. Prudent management of buffers like international reserves and sovereign wealth funds can substantially reduce the real exchange rate volatility associated with terms of trade shocks that affect commodity countries (Aizenman, Edwards, and Riera-Crichton 2012; and Aizenman and Riera-Crichton 2014).

III. EMPIRICAL FRAMEWORK

In this section, we describe the data and empirical framework used for our analysis. We put together data on real GDP growth; country-specific and external shocks; and institutions and fundamentals for a set of high-income, middle-income, and low-income countries spanning 1990–2015. Our final sample period is 2004–2014. Most series are from the Economist Intelligence Unit, Federal Reserve Economic Data, World Economic Outlook (WEO) database, World Development Indicators, and World Trade Flow database, supplemented with series from several sources. Data sources, definitions, and year coverage are provided in the Appendix.

A. Gross Domestic Product Growth and Volatility: A First Look

For our main variables of interests, GDP growth and GDP volatility, we follow the country-income classification in Han and Wei (2015) to classify country observations into income groups:

Extremely low-income economies: GDP per capita (2011 purchasing power parity) < \$1,096
 Low-income economies: \$1,096 < GDP per capita < \$2,527
 Lower-middle-income economies: \$2,527 < GDP per capita < \$5,223
 Upper-middle-income economies: \$5,223 < GDP per capita < \$17,600
 High-income economies: GDP per capita > \$17,600

Of course, the adjustment of GDP growth and volatility does not necessarily follow the same pattern all across countries in an income group. In any case, we will also examine the patterns of data in the whole sample regardless of the income classification.

Figure 4 plots the GDP growth and GDP volatility for each income group. Comparing across income groups, GDP growth of the upper-middle income and high-income countries has shown no tendency to fully recover from the crisis after almost 10 years. These simple plots also suggest that GDP volatility declined in middle-income countries and high-income countries after peaking in 2009–2011, but remains above the level before the crisis.

B. Empirical Approach

The study aims to uncover how countries cope with crises and shocks. We approach the subject by looking at whether better coping mechanisms are associated, on average, with lower volatility of GDP growth, and higher average growth rates. More concretely, the research questions for our empirical analysis are:

- (i) What are the conditions enhancing faster and smoother adjustment of growth to shocks, especially for middle-income countries, before and after a crisis?
- (ii) Is faster and smoother adjustment to shocks associated with higher average growth rate and/or lower output volatility, before and after a crisis?

By and large, greater flexibility of adjustment to external and domestic shocks is likely to help countries sustain growth. More formally, we need to estimate the relationship between flexibility and various factors, including institutions and economic fundamentals. This should allow us to analyze the factors accounting for adjustment of countries to shocks in terms of growth and volatility. The main variables are:

Shocks: Global growth shocks (*globGrwt*), global oil prices (World Texas Intermediate crude as a proxy) (*globOilp*), global financial risk tolerance and volatility (VXO as a proxy) (*globFVol*), wars and civil conflicts (*warConfl*), natural-disaster deaths (*disaster*), and growth spillovers emanating from trade partners (*spillOvr*).

Institutions: Financial openness (*finOpen*), exchange rate stability (*exrStabl*), political stability (*polStabl*), political polarization (*polPolar*), checks and balance (*chknBalc*), rule of law (*ruleoLaw*), and economic freedom (*econFree*).

Fundamentals: Manufacturing output (*manufOut*), foreign reserves (*fxReserv*), working-age population (*wkAgePop*), and schooling (*eduSchlg*).

While the list of controls is not exhaustive, these variables cover the basis for growth and volatility adjustment, and serve the purpose of our study. Our analysis proceeds by:

- (i) studying the natural patterns of growth and volatility adjustment to shocks in the window of the corresponding shock, focusing on the difference between pre-2008 and post-2008 periods, comparing middle-income countries with other income groups; and
- (ii) estimating GDP growth and volatility adjustment, i.e., dependent variables, on a set of domestic and external macroeconomic shocks, and then mapping the estimates and residuals from the growth and volatility estimation to country's institutions and fundamentals.

C. Constructing Growth-Shock Spillovers from Trade Partners

Most of our control variables, shocks, institutions, and fundamentals are readily available for the regression analysis. We construct an additional variable, growth spillovers emanating from trade partners (*spillOvr*), from GDP growth and bilateral trade data. Our data are drawn from the real GDP growth and forecasts from the International Monetary Fund (IMF) WEO database based on semiannual forecasts since 1990. To construct the growth spillover (*spillOvr*),

- (i) We use 2-year historical data and 6-year forecast data of real GDP growth, made available in WEO database (series: *ngdprpch*). Historical data are updated on a continual basis, as more information becomes available, and structural breaks in the data are often adjusted to produce a smooth series with the use of splicing and other techniques. These IMF estimates continue to serve as proxies for historical series when complete information is unavailable. As a result, WEO data can differ from other official data sources, including the IMF International Financial Statistics.
- (ii) We regress real-time 1-period-ahead percent forecast errors for real GDP growth from the WEO database in each country, i.e., the gap at time t of the growth rate of country q from the WEO projection on a set of country and period fixed effects.
- (iii) We take the estimated residual, $e_{q,t}$, from the above regression to capture innovations in real GDP growth orthogonal to professional forecasts and unobserved country and period fixed effects; the residual is a measure of unanticipated growth shocks.

Denoting the growth shock in source country or trade partner q as $e_{q,t}$, measured in percent, we aggregate across countries using bilateral trade as a measure of interdependence

$$spillOvr_{i,t} = \sum_{q \neq i} \frac{W_{iq,B}}{W_{q,B}} \times \{ e_{q,t} \times Y_{q,t-1} \} \quad (2)$$

where $\frac{W_{iq,B}}{W_{q,B}}$ is a weight of independence between source country or trade partner q and recipient

country or country of interest i , scaled by the share of i 's trade in source country q 's total trade. Essentially, we employ a certain factor of trade that translates, directly or indirectly, into bilateral growth spillovers with other countries, which influence the growth adjustment in those countries. We explore scaling by export dependence, i.e., higher growth of importing country trade partner q generates greater demand for i 's output, in our main setup, and also import dependence.

Real GDP growth and forecasts come from the IMF WEO database based on semiannual forecasts since 1990. We estimate impulse responses for three semiannual horizons, starting in the first half of 2004. We use the maximum horizon $H = 2$ and estimate equations for 0–2 periods ahead, with maximum lags $m = 2$. Across countries, the average standard deviation of $\frac{spillOvr_{i,t}}{Y_{i,t-1}} \times 100$ is .642. The average size of these shocks ranges from –3.3 for Hong Kong, China, to –.21 for the US, to .18 for Uruguay. The correlation of shock series varies across countries and trade partners. Countries sharing similar key trading partners tend to have more correlated shock series.

IV. EMPIRICAL RESULTS

In this section, we report and discuss the main findings, which emerge from our empirical analysis.

A. Patterns of Data

From an initial sample of more than 140 countries, combining the variables and dealing with missing values provide us a final sample of 80 countries, covering 2004–2014. Figure 5, which shows the scatter plot of GDP growth and volatility, suggests that there is no clear cluster of growth and volatility pattern based on country-income classifications. To learn more about the natural patterns of data, Figure 6 reports the summary statistics of variables. We pursue a number of different approaches to better understand patterns of data. A couple of key questions emerge. With respect to growth-shock-institution-fundamental associations, do the country observations cluster around the designated country-income classification? In the presence of multicollinearity among controls of growth adjustment estimation, which variables (e.g., shocks, institutions, and fundamentals) explain much of the flexibility of growth adjustment?

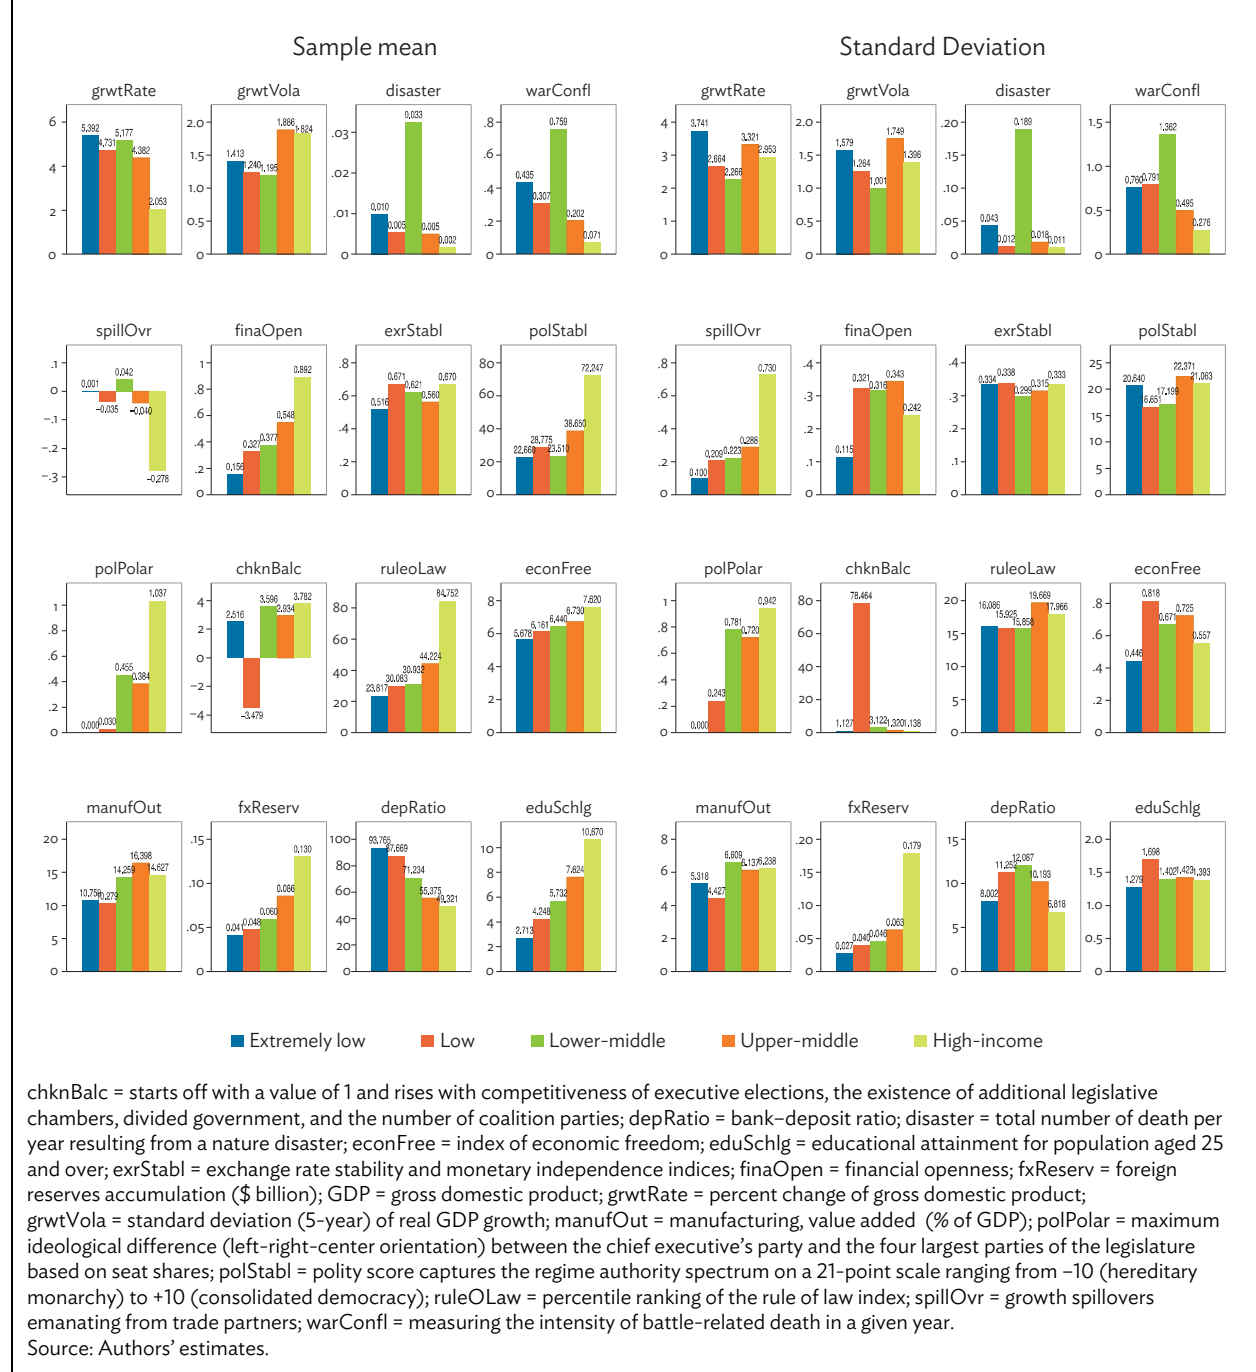

Figure 6: Summary Statistics: Means and Standard Deviations

Looking at the correlations among the variables in Figure 7, several notable patterns emerge. Growth of real GDP is correlated with political stability and educational attainment in both pre-2008 and post-2008 periods. In the aftermath of the global financial crisis, GDP growth has become more correlated with financial openness, exchange rate stability, political polarization, and old age dependency ratio.

Figure 7: Correlation of Variables

depRatio = bank-deposit ratio; disaster = total number of death per year resulting from a nature disaster; eduSchlg = educational attainment for population aged 25 and over; exrStabl = exchange rate stability and monetary independence indices; finaOpen = financial openness; fxReserv = foreign reserves accumulation (\$ billion); GDP = gross domestic product; globFVol = Global Volatility Index (VXO) calculated by the Chicago Board Options Exchange; globGrwt = annual global GDP growth; globOilp = global oil prices (World Texas Intermediate crude as a proxy); grwtRate = percent change of gross domestic product; grwtVola = standard deviation (5-year) of real GDP growth; manufOut = manufacturing, value added (% of GDP); polPolar = maximum ideological difference (left-right-center orientation) between the chief executive's party and the four largest parties of the legislature based on seat shares; polStabl = polity score captures the regime authority spectrum on a 21-point scale ranging from -10 (hereditary monarchy) to +10 (consolidated democracy); spillOvr = growth spillovers emanating from trade partners; warConfl = measuring the intensity of battle-related death in a given year.
 Source: Authors' estimates.

Volatility of GDP growth is correlated with global growth, global financial volatility, and global oil prices in the post-2008 period. Global growth is correlated with global financial volatility and global oil prices. Wars and conflicts are correlated with political stability in both pre-2008 and post-2008 periods. Growth spillovers are correlated with manufacturing output in the pre-2008 period, and with dependency ratio and educational attainment in the post-2008 period. Financial openness is correlated with political stability, political polarization, dependency ratio, and educational attainment in the pre-2008 and post-2008 periods. Political stability is correlated with political polarization, dependency ratio, and educational attainment in both pre-2008 and post-2008 periods. Political polarization is correlated with dependency

ratio and education attainment in both pre-2008 and post-2008 periods. Manufacturing output is correlated with dependency ratio in both pre-2008 and post-2008 periods. Dependency ratio is correlated with education attainment in both pre- and post-2008 periods. The patterns of correlations suggest that most variables are correlated in the pre-2008 and post-2008 periods.

An alternative approach to study the data patterns is to ask how many country groups would fit with the current set of country observations. Based on the multidimensional scaling, shown in Figure 8, it is not clear how the associations of growth-shock-institution fundamental can help classify countries into distinct groups in the pre-2008 and in the post-2008 periods. The evidence seems to suggest that, in terms of growth-shock-institution-fundamental associations, the country observations do not cluster around the designated country-income classification. That is, there is nothing unique in this respect about middle-income countries or other income groups of countries.

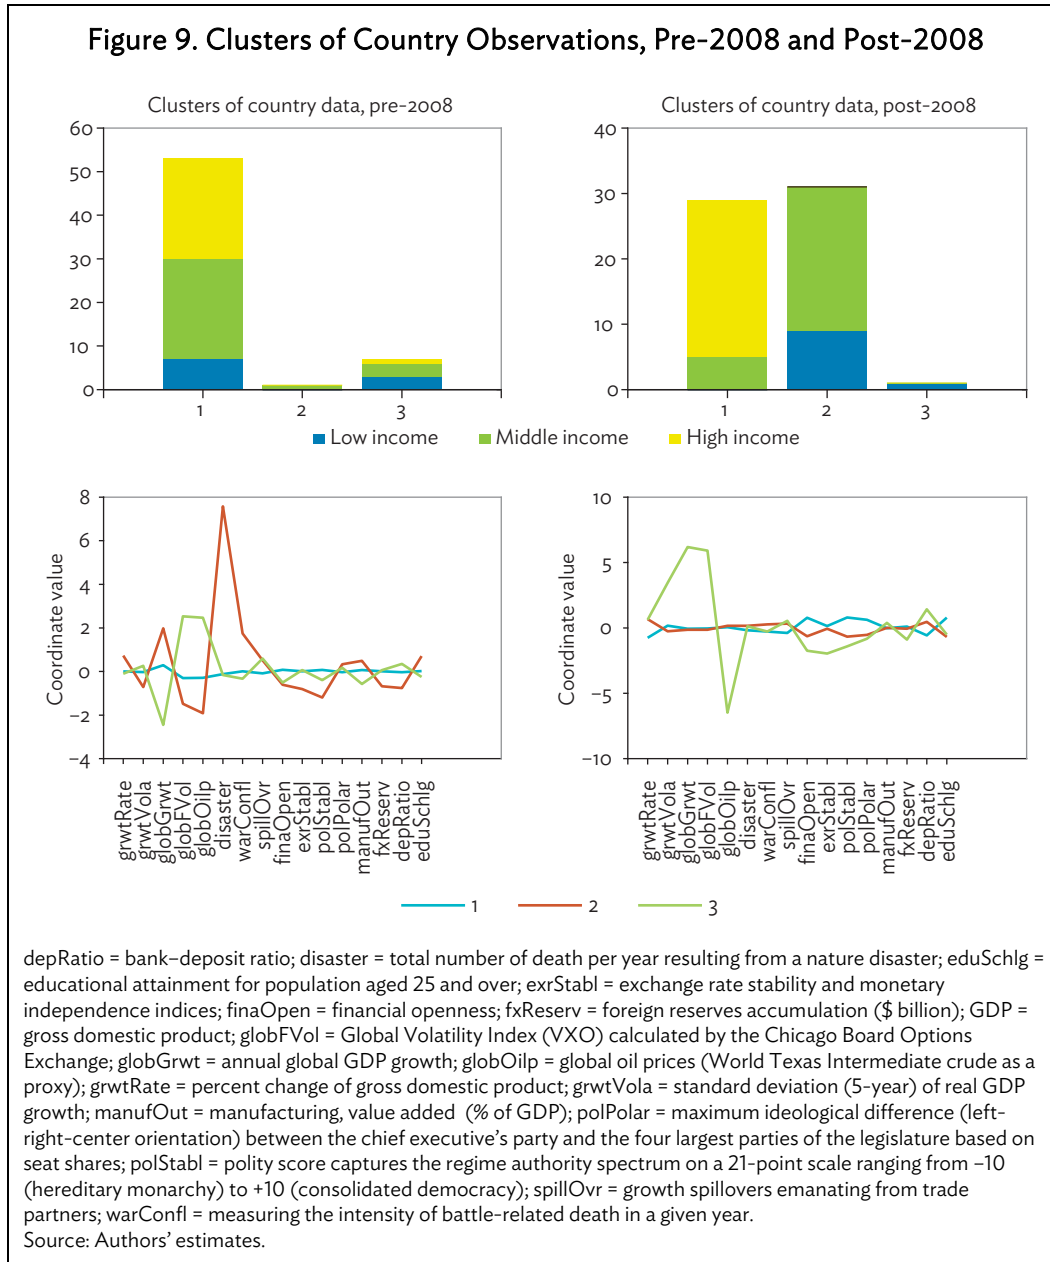

Figure 9 provides an alternative way to cluster the country data. The figure shows clustering analysis of countries based on observed growth, volatility, shocks, institutions, and fundamentals. The alphabetically ordered groups are based on the designated country-income classification, while the numerically ordered groups are based on the clustering analysis. Essentially, the analysis contrasts the designated country-income classification with the patterns of country observations based on all the variables in our sample. In the pre-2008 period, it is not clear if the income grouping fits with a matrix

of variables. For example, based on the macroeconomic characteristics, i.e., growth-shock-institution fundamental, several middle-income countries can be grouped with high-income countries. Similarly, in the post-2008 period, the clustering analysis indicates that income classification does not translate into similar associations of growth, volatility, institutions, and fundamentals of countries in the same designated groupings. A notable result is that global- and country-specific shocks seem to be driving the differences across countries.

Next we look at which variables, i.e., shocks, institutions, and fundamentals, explain much of the movements of GDP growth and volatility in the presence of multicollinearity among control variables. Following Hastie, Tibshirani, and Friedman (2009), the least absolute shrinkage and selection operator estimate is defined by:

$$\hat{\beta}^{lasso} = \arg \min_{\beta} \sum_{it=1}^{NT} \left(y_{it} - \beta_0 - \sum_{j=1}^p x_{it,j} \beta_j \right)^2$$

subject to $\sum_{j=1}^p |\beta_j| \leq z$

where, y_{it} is the dependent variable (GDP growth), x_{it} is the vector of explanatory variables (macroeconomic controls), and z is the size constraint on the parameters corresponding to the amount of shrinkage.

The equivalent Lagrangian form is:

$$\hat{\beta}^{lasso} = \arg \min_{\beta} \left\{ \sum_{it=1}^{NT} \left(y_{it} - \beta_0 - \sum_{j=1}^p x_{it,j} \beta_j \right)^2 + \lambda \sum_{j=1}^p |\beta_j| \right\}$$

Here, λ is the shrinkage (regularization) factor. Note that, unlike the fixed-effect estimation, this setup does not directly account for country-specific fixed effects

Table 1 provides the results of the LASSO estimate for middle-income and high-income countries. For middle-income countries, *globFVol*, *warConfl*, and *GFC* significantly explain the growth adjustment, but none help to explain volatility adjustment. For high-income countries, *globFVol*, *spillOvr*, *finOpen*, *exrStabl*, *fxReserv*, *depRatio*, and *GFC* are significant in accounting for the growth adjustment, whereas *globGrwt*, *globFVol*, *manufOut*, *fxReserv*, *depRatio*, and *GFC* are significant in accounting for the volatility adjustment. The analysis supports the notion that the global financial crisis was a game changer, with global factors and shocks largely driving growth and volatility.

Table 1: Variables that Significantly Explain Growth Adjustment and Volatility Adjustment from the LASSO Estimation

Variables	GDP Growth		Growth Volatility	
	Middle income	High income	Middle income	High income

depRatio = bank-deposit ratio; *disaster* = total number of death per year resulting from a nature disaster; *eduSchlg* = educational attainment for population aged 25 and over; *exrStabl* = exchange rate stability and monetary independence indices; *finOpen* = financial openness; *fxReserv* = foreign reserves accumulation (\$ billion); GDP = gross domestic product; *globFVol* = Global Volatility Index (VXO) calculated by the Chicago Board Options Exchange; *globGrwt* = annual global GDP growth; *globOilp* = global oil prices (World Texas Intermediate crude as a proxy); *manufOut* = manufacturing, value added (% of GDP); *polPolar* = maximum ideological difference (left-right-center orientation) between the chief executive's party and the four largest parties of the legislature based on seat shares; *polStabl* = polity score captures the regime authority spectrum on a 21-point scale ranging from -10 (hereditary monarchy) to +10 (consolidated democracy); *spillOvr* = growth spillovers emanating from trade partners; *warConfl* = measuring the intensity of battle-related death in a given year. Notes: x means that the variable is significant. *GFC* is equal to 1 for the years 2009–2014 and 0 otherwise. Source: Authors' estimates.

B. Panel Estimation

More specifically, we want to estimate the associations between the dependent variable, i.e., GDP growth and GDP volatility, and domestic and external shocks as well as GDP growth spillovers from trade partners, using direct projections from a series of regressions for different horizons, $h = 0, \dots, H$

$$(1) \quad Y_{i,t+h} - Y_{i,t+1} = \sum_{s=1}^m \beta_{hs} \Delta Y_{i,t-s} + \sum_{s=1}^m \delta_{hs} X_{i,t-s} + \alpha_h \frac{spillOvr_{i,t}}{Y_{i,t+1}} + \phi_{hi} + \mu_{ht} + \varepsilon_{iht}$$

where Y denotes the dependent variable (GDP growth, GDP volatility), X is a vector of controls (domestic and external shocks), ϕ and μ are horizon-specific country and time fixed effects, $spillOvr$ is the measure of growth spillovers emanating from trade partners, i stands for country, and t stands for time period. Impulse response for H periods is constructed from a sequence of estimated $\left[\alpha_h \right]_{h=0}^H$.

Table 2 reports the GDP growth and volatility accounted for by shocks and growth spillovers emanating from trade partners, i.e., top importing countries. The coefficient estimates are reported with standard errors in parentheses. The first two columns report the growth estimates for the whole sample, split into pre-2008 and post-2008 periods, while the following two columns report estimates for the middle-income sample. The estimation results suggest that global growth (+), global financial volatility (+), and global oil prices (-) are associated with country growth in the pre-2008 period, while global growth (+), global financial volatility (-), and global oil prices (+) are associated with country growth in the post-2008 period. These qualitative results are applicable to the whole sample and the middle-income sample. The overall explanatory power is a quarter to a third in this set of estimations.

The second half of Table 2 reports the growth volatility estimation. The coefficient estimates are reported with standard errors in parentheses. The estimation results suggest that global growth (-), global financial volatility (-), global oil prices (+), and natural disaster (+) are associated with growth volatility in the pre-2008 period, while global growth (-), global financial volatility (+), and global oil prices (-) are associated with growth volatility in the post-2008 period. For the middle-income sample, the estimation results are qualitatively similar. The overall explanatory variable is about a tenth to a quarter in this set of estimations.

Focusing on the associations between GDP growth and growth spillovers from trade partners, it is useful to look at the impulse responses of growth over a number of time periods. Table 3 reports the average growth spillovers from trade partners' growth shocks over three periods, $\frac{1}{3} \sum_h \alpha_h; h = 0, 1, 2$, with standard errors in parentheses. The calculation is done using different trade weights—all top trade partners in the first column, top importers in the second column, and top exporters in the third column. The results suggest that growth shocks emanating from trade partners are associated with growth spillovers (+) in the pre-2008 period, but become much less significant in the post-2008 period.

To identify the conditions that drive faster and smoother adjustment of growth to shocks for middle-income countries in the 2004–2014 period, we correlate the estimated residuals of growth and volatility, controlling for domestic and external shocks, with institutions and economic fundamentals, measured by their coefficient of variation over 5-year periods. Figure 10 shows that shock-adjusted

growth is positively associated with higher educational attainment, manufacturing output, and exchange rate stability, while the shock-adjusted volatility is positively associated with higher exchange rate stability and polarization, and lower educational attainment.

Focusing on the most significant variables, Figure 11 plots the data between two subperiods for middle-income countries. The scatterplots suggest that economic fundamentals, such as manufacturing output to GDP ratio and educational attainment showed persistent pattern over the years, while institutional factors, such as exchange rate stability and political polarization, changed significantly between 2003–2007 and 2010–2014 across middle-income countries. Understanding the country-specific persistence and evolution over time of these variables is, therefore, useful in accounting for the adjustment of GDP growth and volatility.

V. CONCLUDING OBSERVATIONS

In this paper, we examine how economic growth and growth volatility are associated with internal and external shocks, as well as shock spillovers from trade partners, before and after the global financial crisis, taking into account country-specific economic institutions and fundamentals. Flexibility of growth adjustment is an issue of high and growing importance, especially against the background of postcrisis global growth slowdown and heightened political and policy uncertainties. The vulnerability of middle-income countries to shocks is an interesting issue since these countries are typically more integrated into the world economy but, unlike most high-income countries, often lack well-established policies and institutions to cope with shocks.

Our analysis examines and compares the role of institutions and fundamentals on the adjustment of growth and volatility to shocks in the precrisis and postcrisis periods. Empirical analysis of panel data of high-income, middle-income, and low-income countries over 2004–2014 shows that the associations of growth, volatility, shocks, institutions, and economic fundamentals have changed in

important ways after the crisis. More specifically, we find that GDP growth across all income groups of countries has become more dependent on external factors, including global growth, global oil prices, and global financial volatility. In addition, despite the slowdown of global trade after the crisis, there is evidence that growth spillovers from trade partners have economically significant effects on country's growth. There is nothing unique about the exposure of middle-income countries to such global shocks.

A country's response and adjustment to shocks depend on several factors—age dependency ratio and foreign reserves, to name just two. After accounting for the effects from global shocks, for middle-income countries we identify some factors that facilitate adjustment to shocks, in terms of growth and volatility. Higher educational attainment, higher manufacturing output in GDP, and higher exchange rate stability increase economic growth. Lower political polarization, higher exchange rate flexibility, and higher educational attainment reduce the volatility of economic growth. Therefore, overall, our cross-country findings suggest that countries can cope with shocks better in the short to medium term by appropriately using flexible policy tools; for instance, greater exchange rate flexibility help reduce growth volatility, as well as maintaining solid long-term fundamentals; and higher education and lower political polarization help reduce growth volatility.

Flexibility of Adjustment to Shocks: Economic Growth and Volatility of Middle-Income Countries Before and After the Global Financial Crisis of 2008

This paper examines how economic growth and growth volatility are associated with internal and external shocks, as well as shock spillovers from trade partners, taking into account the country's economic institutions and fundamentals. It finds that the associations of growth, volatility, shocks, institutions, and macro fundamentals have changed in important ways after the recent global financial crisis. In particular, gross domestic product growth across countries has become more dependent on external factors, including global growth, global oil prices, and global financial volatility.

About the Asian Development Bank

ADB's vision is an Asia and Pacific region free of poverty. Its mission is to help its developing member countries reduce poverty and improve the quality of life of their people. Despite the region's many successes, it remains home to a large share of the world's poor. ADB is committed to reducing poverty through inclusive economic growth, environmentally sustainable growth, and regional integration.

Based in Manila, ADB is owned by 67 members, including 48 from the region. Its main instruments for helping its developing member countries are policy dialogue, loans, equity investments, guarantees, grants, and technical assistance.
